Highlights:

- New bentonite $^{40}\text{Ar}/^{39}\text{Ar}$ dates yield revised Cenomanian-Turonian Boundary (CTB) age
- New rhenium-osmium geochemistry of Angus and SH#1 cores in Western Interior Basin
- Rapid pre-OAE2 initial Os isotope excursions mark large igneous province volcanism
- 59 ± 10 kyr lag between LIP volcanism and global net organic C burial at OAE2 onset
- Quantified duration of basal OAE2 hiatus in the Base Turonian GSSP section at Pueblo, CO

Keywords:

- Ocean Anoxic Event 2, geochronology, Cenomanian-Turonian stage boundary, large igneous province volcanism, osmium chemostratigraphy, Western Interior Seaway

26 Abstract

27 Fluctuations in depositional conditions during the onset of severe climate events in Earth history
28 predispose stratigraphic archives to hiatuses, often hindering complete reconstructions of
29 paleoclimate events and their triggers. Several studies have proposed that a hiatus of unknown
30 duration exists at the base of Oceanic Anoxic Event 2 (OAE2) in the North American Western
31 Interior Basin (WIB) at the Base Turonian Global Boundary Stratotype Section and Point (GSSP)
32 in Pueblo, Colorado, potentially influencing integrated radioisotopic, biostratigraphic, and
33 astrochronologic age models of the Cenomanian-Turonian boundary (CTB) interval. To quantify
34 the duration of this hiatus, refine the chronology of OAE2, and assess marine geochemical
35 perturbations associated with the onset of the event, we present new $^{40}\text{Ar}/^{39}\text{Ar}$ dates from regional
36 CTB interval bentonites along with a new proximal-distal chemostratigraphic transect of the
37 epeiric WIB, including rhenium-osmium and stable carbon isotope data. The new $^{40}\text{Ar}/^{39}\text{Ar}$ age
38 determinations confirm and further constrain previous estimates of CTB timing. Initial osmium
39 isotope ratio (Os_i) studies of OAE2 at globally distributed sites record prolific large igneous
40 province (LIP) volcanic activity 10's of kyr prior to the carbon isotope ($\delta^{13}\text{C}$) excursion of OAE2.
41 However, a recent chemostratigraphic study observed minimal stratigraphic offset between Os_i
42 and $\delta^{13}\text{C}$ excursions in a Re-Os record near the Base Turonian GSSP in the central WIB,
43 confirming a hiatus. In contrast, the new Os_i chemostratigraphy of the Angus Core (Denver Basin)
44 and SH#1 Core (S. Utah) exhibit more characteristic stratigraphic lags between Os_i and $\delta^{13}\text{C}$
45 excursions, indicating stratigraphic expansion and conformability across the onset of the event at
46 other sites in the WIB. An existing astronomical time scale for the Angus Core quantifies the
47 temporal lag between LIP volcanism and the beginning of OAE2 (59 ± 10 kyr) and constrains the
48 duration of the hiatus in the Portland Core as geologically brief, indicating that the stratigraphic

49 record at the GSSP locality is largely conformable through OAE2. This astronomically-tuned
50 conformable $\delta^{18}O_i$ record across the onset of OAE2 captures a geologically rapid onset of LIP
51 volcanism, consistent with other records, such that the addition of CO_2 to the ocean-atmosphere
52 system may have driven changes in marine carbonate chemistry. Additionally, the refined
53 chronostratigraphy of OAE2 and the CTB in the central WIB improves correlation with other
54 records, such as those in the Eagle Ford Group, Texas. The correlations highlight that discrepancies
55 among OAE2 age models from globally distributed sections commonly stem from differing
56 definitions of the event and uncertainties associated with astronomical tuning, in addition to
57 stratigraphic preservation.

INTRODUCTION AND BACKGROUND

Resolving the causal mechanisms of major paleoclimate and paleobiotic events in Earth history is critical to understanding the vulnerabilities of modern and ancient ecosystems. However, the extreme changes in depositional environments associated with the onset of many mass extinction events and carbon cycle perturbations, such as sea level fluctuations or ocean acidification, may result in hiatal surfaces that obscure geological evidence of the processes initiating such events (Smith et al., 2001; Holland and Patzkowsky, 2015; Baresel et al., 2017). Expanded, or at least relatively continuous, stratigraphic successions with robust time control are, therefore, key to reconstructing climate change in the geologic record. This study investigates the onset of Oceanic Anoxic Event 2 (OAE2, ~94 Ma), a significant Late Cretaceous carbon cycle perturbation lasting over half a million years, through a proximal-distal chemostratigraphic transect of the shallow marine Western Interior Basin (WIB) of North America. It assesses stratigraphic conformability at reference sites such as the Base Turonian Stage Global Boundary Stratotype Section and Point (GSSP) in Pueblo, Colorado, and refines the timing of changes in volcanic activity, global geochemical cycles, and sea level spanning the onset of OAE2.

Episodes of voluminous volcanism emplacing large igneous provinces (LIPs) commonly precede, or are broadly contemporaneous with, carbon cycle perturbations and mass extinctions through geologic time (Wignall, 2001; Turgeon and Creaser, 2008; Kidder and Worsley, 2010). As a result, elemental and isotopic paleoceanographic proxies sensitive to volcanic fluxes may identify the initiation of such events, as well as elucidate a causal linkage between LIPs and perturbation of the carbon cycle. Moreover, they provide potential chemostratigraphic markers to define the relative expansion or condensation of stratigraphic intervals during the onset of such events, arguably the critical phase for determination of causal factors. This is especially the case

for isotopic systems with short marine residence times (τ) that capture rapid changes in geochemical fluxes (e.g., Kuroda et al., 2007; Percival et al., 2018). The osmium reservoir of the global ocean mixes over geologically brief time scales ($\tau < 30$ kyr, Oxburgh, 2001; Rooney et al., 2016) and, at the time of deposition, initial marine osmium isotope ratios ($^{188}\text{Os}/^{187}\text{Os}_{\text{(initial)}} = \text{Os}_i$) principally record changes in the relative fluxes of osmium from two isotopically distinct end members, continental weathering ($\text{Os}_i = \sim 1.4$) and hydrothermal inputs ($\text{Os}_i = 0.13$) (Peucker-Ehrenbrink and Ravizza, 2000). Consequently, the Os_i proxy has resolved anomalous increases in volcanic activity across many Mesozoic climate transitions, including OAEs, the Triassic-Jurassic Boundary, and the Cretaceous-Paleogene Boundary (Ravizza and Peucker-Ehrenbrink, 2003; Kuroda et al., 2010; Bottini et al., 2012).

For OAE2, the discovery of an abrupt unradiogenic Os_i excursion at the base of the event (Turgeon and Creaser, 2008) provides strong evidence for the hypothesis that hydrothermal inputs, likely emanating from the Caribbean LIP and potentially the High Arctic LIP, triggered an Earth system response that ultimately led to expanded bottom water anoxia and elevated organic carbon burial (Sinton and Duncan, 1997; Kerr, 1998; Snow et al., 2005; Adams et al., 2010; Barclay et al., 2010; Owens et al., 2013). The OAE2 Os_i excursion is also recorded in numerous disparate basins, confirming the proxy as a globally correlative marine chemostratigraphic marker and highlighting a temporal lag, on the order of tens of kiloyears, between the onset of the Os_i excursion and the younger carbon isotope ($\delta^{13}\text{C}$) excursion (Turgeon and Creaser, 2008; Du Vivier et al., 2014; Du Vivier et al., 2015b; Schröder-Adams et al., 2019; Sullivan et al., in press). This lag likely reflects the fundamental response time of the Earth's carbon cycle to a massive pulse of CO_2 to the ocean-atmosphere system from LIP volcanism.

To assess the potential explanations and implications of this lag, and to quantify its duration, this study presents new Os_i chemostratigraphic records of the OAE2 onset interval in the WIB from the Angus Core in north-central Colorado and the SH#1 Core in southern Utah (Fig. 1). New $^{40}\text{Ar}/^{39}\text{Ar}$ dating of regionally correlated bentonites, along with existing radioisotopic ages, astrochronology, and $\delta^{13}\text{C}$ chemostratigraphy (Meyers et al., 2012b; Ma et al., 2014; Jones et al., 2019), provide tight age control at these locales for comparison with the Base Turonian GSSP in Pueblo, Colorado, as well as refine the timing and sequence of marine geochemical events through the onset of OAE2. A previous Os_i chemostratigraphy of the Portland Core, near the GSSP locality, does not exhibit the full characteristic lag between Os_i and $\delta^{13}\text{C}_{\text{org}}$ preserved in many other records globally (Du Vivier et al., 2014). This chemostratigraphic feature suggests that a hiatus exists at the base of OAE2 in the GSSP. As a result, some recent studies have questioned the stratigraphic completeness of the CTB records from the mid-latitudes of the WIB and suggested that critical time intervals of OAE2 may be missing at the GSSP (Eldrett et al., 2017; Li et al., 2017; Scott et al., 2018). Thus, the new Os_i chemostratigraphic transect of the WIB presents an opportunity to constrain the spatial extent, origin, and duration of this stratigraphic gap and to evaluate the hypothesis that a crucial interval of time is missing from sedimentary records of OAE2 in the central WIB, including at the GSSP locality.

GEOLOGIC SETTING AND MATERIALS

Cenomanian-Turonian Stratigraphy in the Western Interior Basin

The Late Cretaceous Greenhorn Cyclothem of the foreland Western Interior Basin preserves a ~10-Myr succession of shallow marine facies; OAE2 spans the CTB and occurs just prior to the Early Turonian peak highstand (maximum transgression) of the cyclothem (Kauffman

and Caldwell, 1993). This highstand of the seaway inundated the North American craton and linked the proto-Gulf of Mexico to the arctic Boreal Sea, ranging longitudinally from present-day Iowa to central Utah (Fig. 1). Uplift along the Sevier thrust belt generated maximum subsidence in the proximal western foredeep of the basin, providing accommodation space and sediment supply that produced relatively expanded records of OAE2, such as in the Tropic Shale of the SH#1 Core near Big Water, Utah (Jones et al., 2019). Further east, in the more distal “axial basin” of Colorado and the “stable craton” of the central plains (*sensu* Kauffman, 1984), the hemipelagic sediments of the Bridge Creek Limestone accumulated more slowly and are more carbonate-rich. This is the case in the Angus Core of the Denver Basin, studied here, and in the Portland Core, near the Base Turonian GSSP at the Rock Canyon Anticline in Pueblo, Colorado (Figs. 1-2). A chronostratigraphic framework to correlate these proximal-distal mid-latitude regions of the WIB comprises: areally expansive and radioisotopically dated bentonites (“bentonites A-D”; Elder, 1988; Obradovich, 1993; Meyers et al., 2012b), ammonite, inoceramid, and microfossil biostratigraphy (Leckie, 1985; Bralower, 1988; Elder, 1989; Elder, 1991; Kauffman et al., 1993; Kennedy et al., 2005; Corbett and Watkins, 2013), astrochronology from climatically sensitive lithologic patterns (Sageman et al., 1997; Meyers et al., 2001; Ma et al., 2014; Jones et al., 2019), lithostratigraphy (Hattin, 1971; Cobban and Scott, 1972; Elder et al., 1994; Elderbak and Leckie, 2016), and carbon isotope chemostratigraphy (Pratt and Threlkeld, 1984; Pratt et al., 1993; Sageman et al., 2006; Joo and Sageman, 2014).

Prior to OAE2, during deposition of the late Cenomanian Hartland Shale in the axial basin, the seaway was relatively oxygen-depleted, restricted, and conducive to organic carbon burial (Eicher and Worstell, 1970; Sageman, 1985; Sageman, 1989; Meyers et al., 2001; Sageman et al., 2014a; Eldrett et al., 2017). The lower Bridge Creek Limestone overlies the Hartland Shale in the

Angus and Portland cores (Fig. 2) of the axial basin and preserves the carbon isotope excursion (CIE) that defines OAE2 globally (Pratt et al., 1993). The shift to more calcareous, rhythmically bedded lithologies above the basal contact of the Bridge Creek follows a transgression and pronounced backstepping of the basin's shoreline along the seaway's western margin in southern Utah (Kauffman, 1977; Laurin and Sageman, 2007). This deepening is associated with development of a more oxic watermass in the seaway during early OAE2 deposition in the lower Bridge Creek (Eicher and Worstell, 1970; Eicher and Diner, 1985, 1989; Arthur and Sageman, 1994; Savrda and Bottjer, 1994; Sageman et al., 1997; Eldrett et al., 2017), contrasting with anoxic conditions in many proto-Atlantic and Tethyan sites during the event (Schlanger et al., 1987).

Along the western paleo-margin of the seaway in southern Utah, the fossiliferous Tropic Shale overlies the Naturita Sandstone (Young, 1965; Peterson, 1969; Uličný, 1999), a unit that was, until recently, designated the Dakota Sandstone following standard lithostratigraphic convention for the WIB (Carpenter, 2014). The SH#1 Core, drilled near Big Water, UT on the Kaiparowits Plateau, records an apparently continuous succession of proximal calcareous shales through OAE2 and the CTB (Jones et al., 2019). Thin traceable carbonate-rich beds also occur within the OAE2 interval of the lower Tropic Shale in SH#1 and nearby outcrops, such as the Nipple Creek outcrop section sampled in this study for $^{40}\text{Ar}/^{39}\text{Ar}$ bentonite dating. The carbonate beds preserve evidence of partial diagenetic alteration within the expanded $\delta^{13}\text{C}$ chemostratigraphy of the SH#1 Core. This diagenesis relates to eccentricity paced relative sea level cycles and flooding surfaces (Jones et al., 2019), which grade westward to shoreface parasequences (Laurin et al., 2019) and eastward to the rhythmically bedded marlstone-limestone couplets of the Bridge Creek in the axial basin (Elder et al., 1994). The combined astrochronology, microfossil datums, bentonite A-D stratigraphy, expanded $\delta^{13}\text{C}$ chemostratigraphy (Jones et al., 2019), and ammonite

biostratigraphy from outcrops on the Kaiparowits Plateau region (Elder, 1989) form a chronostratigraphic framework for the SH#1 Core within which our new Os_i chemostratigraphy and ⁴⁰Ar/³⁹Ar geochronologic data are incorporated.

OAE2 Hiatuses in the Central Western Interior Basin

The Bridge Creek and uppermost Hartland Shale in the Portland Core and GSSP exhibit evidence for hiatal surfaces at two horizons (Fig. 5). The first hiatal surface, identified by spectral analyses and quantified to be <20 kyr, occurs near the base of the ammonite *Neocardioceras juddi* Biozone (Meyers and Sageman, 2004). The second hiatus, a focus of this study, is associated with a phosphatic bone bed at the base of the CIE and 55 cm below the thick lowermost Bridge Creek limestone bed (Bed 63 or LS1) (Pratt, 1984; Eicher and Diner, 1989), which defines the members' contact (Cobban and Scott, 1972; Elder and Kirkland, 1985). This unquantified hiatus (Du Vivier et al., 2014) falls at the critical OAE2 onset interval (Fig. DR4 in the GSA Data Repository¹).

METHODS

Re-Os Geochemistry

Existing $\delta^{13}\text{C}$ chemostratigraphic profiles guided high-resolution sampling for rhenium-osmium geochemical analyses through the onset of OAE2 from the SH#1 Core (n=20, median spacing = 50 cm) and the Angus Core (n=15, median spacing = 30 cm). See Data Repository for details on sample collection and alignment of the Angus Core depth scale with previous studies. Prior to analysis at Durham University, samples were powdered in ceramic containers using high-purity crushing techniques (Ottawa sand pre-clean) at Northwestern University. Following the

methodology of Selby and Creaser (2003), sample powders were spiked with a $^{185}\text{Re}+^{190}\text{Os}$ tracer solution and digested in sealed Carius tubes with 8 mL of 0.25 g/g CrO_3 in 4N H_2SO_4 for ~48 hours at 220°C, principally leaching hydrogenous Re and Os (i.e., carbonates and organic matter). The Re fraction was isolated via NaOH-acetone extraction and anion chromatography. The Os fraction was isolated and purified via chloroform extraction with back reduction into HBr and $\text{CrO}_3\cdot\text{H}_2\text{SO}_4\text{-HBr}$ microdistillation. Isotopic ratios of samples and standards were measured on a Triton TIMS in negative ionization mode. The average 2σ precision for Os_i values was ± 0.014 (max = ± 0.057). Present-day measured $^{187}\text{Os}/^{188}\text{Os}$ values of samples were corrected to initial osmium ratios (Os_i) by accounting for post-depositional beta decay of ^{187}Re ($\lambda = 1.666\times 10^{-11}\text{yr}^{-1}$; Smoliar et al., 1996) using an age of 94.4 Ma for the onset of OAE2.

$^{40}\text{Ar}/^{39}\text{Ar}$ Geochronology

Bulk samples of regional bentonites B, C, and D of (Elder, 1988) were collected from the Nipple Creek (NC) outcrop section in southern Utah 13 km WSW of the SH#1 Core (Fig. DR3 in the Data Repository). Bentonites were identified via the local lithostratigraphy of the CTB interval (Elder, 1991) and an impression of ammonite *N. juddi* confirmed the Bentonite B horizon. Two additional $^{40}\text{Ar}/^{39}\text{Ar}$ dates were obtained from samples of bentonites C and D previously collected and analyzed from Pueblo, Colorado (K-07-01C) and Lohali Point, Arizona (90-O-34) (Obradovich, 1993; Meyers et al., 2012b). Sanidine was isolated via magnetic and density sorting techniques and its composition verified using a variable pressure scanning electron microscope. Sanidine separates were irradiated for 65 hours along with the 28.201 Ma Fish Canyon Tuff sanidine (Kuiper et al., 2008) in the CLICIT facility of the Oregon State University TRIGA reactor. In the WiscAr Laboratory at the University of Wisconsin-Madison, individual sanidine crystals

from each of the Nipple Creek bentonites were incrementally heated using a 50W CO₂ laser and the extracted gas analyzed using a Nu Instruments Noblesse multi-collector mass spectrometer following Jicha et al. (2016). Single crystal total fusion experiments were performed for samples K-07-01C and 90-O-34. Dates were calculated using the decay constants of Min et al. (2000) and reported with uncertainties as $\pm X/Y$ at the 95% confidence level with: (X) analytical sources of uncertainty including the J uncertainty and (Y) full external sources of uncertainty, including standard age and decay constants.

RESULTS

Re-Os Geochemistry

The new records from the Angus and SH#1 cores reproduce an abrupt, unradiogenic Os_i excursion that spans the onset of OAE2, similar to the Portland Core Os_i record (Du Vivier et al., 2014). Unlike the Portland Core record, however, both the SH#1 and Angus cores preserve strata between the bases of the Os_i and $\delta^{13}\text{C}$ excursions, as is documented in other conformable records of the OAE2 onset, such as the expanded Pont'd Issole section of southern France (Du Vivier et al., 2014). The Os_i excursion occurs below the base of the carbon isotope excursion (CIE) by 131 \pm 22 cm in the SH#1 Core at 122.29 m and by 80 \pm 25 cm in the Angus Core at 2279.98 m (Figs. 3-4 and Fig. DR4). The unradiogenic Os_i shift occurs in the SH#1 Core at a flooding surface (“fs2a” of Elder et al., 1994) (Fig. 4) and in the Angus Core in the uppermost calcareous shales of the Hartland Member.

Minimum values of Os_i at each Western Interior locality (SH#1 = 0.149 ± 0.006 , Angus = 0.167 ± 0.002 , Portland = 0.156 ± 0.003) approach the hydrothermal end member of the osmium isotope system ($^{187}Os/^{188}Os_{\text{hydrothermal}} = 0.13$; Peucker-Ehrenbrink and Ravizza, 2000). However, the magnitude of the Os_i excursion is significantly larger in the proximal SH#1 Core ($\Delta Os_i = 1.30$) than in the Portland Core ($\Delta Os_i = 0.78$; Du Vivier et al., 2014) and the Angus Core ($\Delta Os_i = 0.74$), due to more radiogenic Os_i values preceding the event (max. Os_i in SH#1 = 1.446 ± 0.039 vs. Angus = 0.910 ± 0.027) (Fig. 5).

The astronomical time scale for the Angus Core (Ma et al., 2014) constrains the duration of the temporal lag between the Os_i excursion and the base of the OAE2 CIE to 2.9 ± 0.5 precessional cycles, equivalent to 59 ± 10 kiloyears (Fig. 5). The Os_i and $\delta^{13}C$ excursions are nearly superimposed in the Portland Core, whereas initiation of the $\delta^{13}C$ shift lags the Os shift at the two other WIB sites. This observation supports the hypothesis of a hiatus in the Pueblo area and permits the duration of missing time to be quantified. Equivalent to the duration of the lag, the hiatus represents ~ 60 kyr (see Discussion). Based on the established astrochronology of the Angus Core, values of Os_i remain unradiogenic for 172-257 kiloyears spanning the ammonite *Sciponoceras gracile* Biozone at the beginning of OAE2 (Fig. 6).

Broadly correlative enrichments of Os , best represented by ^{192}Os concentration data, occur through the onset of OAE2 in all WIB sites (Figs. 2-3). Concentrations of ^{192}Os in the Angus Core are significantly enriched (max $[^{192}Os] = 1183.9 \pm 4.3$ ppt) by roughly an order of magnitude compared to the SH#1 Core (max $[^{192}Os] = 162.3 \pm 0.9$ ppt) (Table 1). Elevated ^{192}Os concentrations occur throughout the duration of the unradiogenic Os_i excursion.

Concentrations of Re in the Angus Core are highest in the uppermost Hartland Shale (max $[Re] = 89.31 \pm 0.22$ ppb) in the ~ 60 kiloyears prior to OAE2 and exceed the background levels of

~50 ppb (Table 1; Figs. 4, 6). Similar to records from the Portland Core (Du Vivier et al., 2014), Re concentrations in the Angus Core decrease markedly above the Hartland Shale-Bridge Creek Limestone contact and during the main body of the OAE2 CIE. Like ^{192}Os , concentrations of Re are elevated in the central axial basin localities compared to the SH#1 core where Re concentrations do not exceed 14 ppb despite enrichment during the Os_i excursion.

$^{40}\text{Ar}/^{39}\text{Ar}$ Geochronology

The $^{40}\text{Ar}/^{39}\text{Ar}$ analyses yield five new precise sanidine $^{40}\text{Ar}/^{39}\text{Ar}$ dates for bentonites B, C and D (Table 2; Fig. 7). Incremental heating experiments produce plateau dates in most cases, with only one being markedly older than the population of plateau dates for a given sample. The weighted mean ages for each bentonite obey superposition and the ages for the B and C bentonites from different localities are indistinguishable (Table 2). Full analytical results and Ar plots can be found in the Data Repository (Tables DR4-5).

DISCUSSION AND IMPLICATIONS

Assessing Conformability of the Base Turonian GSSP

An integrated chronostratigraphic framework of radioisotopic age dates, astrochronology, chemostratigraphy, and biostratigraphy spans the Cenomanian-Turonian boundary (CTB) interval at the Base Turonian GSSP at Rock Canyon Anticline in Pueblo, Colorado, constraining rates of change in geochemical and paleobiologic datasets from the Western Interior Seaway during OAE2 (Kennedy et al., 2005; Sageman et al., 2006 and refs therein). This high-resolution age control has

aided in quantifying a cryptic 17 kyr hiatus above the LS5 bed of Elder et al. (1994) in the Bridge Creek Limestone Member (Meyers and Sageman, 2004) and has also indicated the presence of a second hiatus at the base of OAE2 at the GSSP section, assessed in this study (Fig. 5). This basal OAE2 hiatus occurs as a distinct 0.5 cm “thin wavy-bedded layer” in the uppermost Hartland Shale with phosphatized bones and scoured quartz sand at the GSSP (Pratt, 1984). These sedimentological characteristics, along with a sharp influx of benthic foraminifera with Tethyan affinity in the overlying uppermost marlstone bed of the Hartland Shale, allude to a marked shift in paleoenvironmental conditions which Eicher and Diner (1989) hypothesized to represent a hiatus. More recently, Os_i chemostratigraphy of the nearby Portland Core (Fig. 5) detected that the unradiogenic Os_i excursion preceding OAE2 directly underlies the base of the event’s CIE and lacks the characteristic stratigraphic lag between Os_i and $\delta^{13}\text{C}$ excursions of the event globally (Du Vivier et al., 2014). This chemostratigraphic feature confirmed the presence of a hiatus (Fig. DR4 in Data Repository) that has the potential to impact geochemical reconstructions of the critical OAE2 onset interval and precise Earth system responses to the event’s trigger (see discussion in Du Vivier et al., 2015a; Eldrett et al., 2017). However, the duration of the hiatus at the base of the OAE2 CIE at the GSSP section and Portland Core remained unquantified prior to this study.

Lithostratigraphic correlations of the hemipelagic marlstone-limestone couplets of the CTB interval in the central WIB reveal that the LS1 bed of the Bridge Creek at the GSSP and Portland Core is condensed (Ma et al., 2014). The bed expands into multiple couplets south and north of Pueblo, at the Greenhorn Creek outcrop and in the Angus Core of the Denver Basin, respectively (Fig. 5). Additionally, the new Os_i chemostratigraphy of the CTB interval from both the SH#1 Core and the astronomically-tuned Angus Core exhibit an expanded stratigraphic interval between the Os_i excursion and base of the OAE2 CIE (Figs. 3-5). These observations

signify that more continuous sedimentation existed elsewhere in the region across the onset of OAE2 compared to the GSSP locality and, further, they constrain the duration of the hiatus at the GSSP section to 59 ± 10 kyr (Fig. 5). Summing the quantified hiatuses above LS5 and at the base of OAE2, we estimate that the GSSP section is missing 82 ± 10 kiloyears in detectable hiatal surfaces (i.e., hiatuses of ≥ 10 s kiloyears in duration). This suggests that the GSSP section preserves ~90% of the temporal duration of the broader OAE2 interval from the O_{Si} excursion to CIE termination.

Although the GSSP section is conformable spanning the Cenomanian-Turonian stage boundary, adhering to criteria for GSSPs, the hiatus at the onset of OAE2 in this site omits a brief time interval. This interval, however, is represented in other sections within the basin that can be readily correlated to the GSSP site, such as the Angus and SH#1 cores.

OAE2 Time Scale Comparisons

Oceanic Anoxic Event 2, which was first identified as a black shale succession spanning the Cenomanian-Turonian boundary at many marine sites (Schlanger and Jenkyns, 1976; Arthur et al., 1987), can be recognized globally by a prominent positive carbon isotope excursion (CIE) (Scholle and Arthur, 1980). Defining OAE2 from the base of this CIE to a return to stable background $\delta^{13}C$ values at the top of the event (the “long” definition, as compared to the shorter “end of CIE plateau” definition: Tsikos et al., 2004; Sageman et al., 2006), recent studies from the Iona-1 Core in the Maverick Basin of Texas and in Gongzha, Tibet found comparatively expanded durations of OAE2 of 920 ± 170 kyr and 820 ± 25 kyr, respectively (Eldrett et al., 2015; Li et al., 2017). Compared to syntheses from the Western Interior Basin, these recent findings are

equivalent in duration to the long definition values of 866 ± 19 kyr (Sageman et al., 2006). However, to reconcile the nominal offsets in mean durations, authors have noted the occurrence of pre-cursor isotopic events in the Iona-1 Core of Texas and stratigraphic expansion in Tibet, proposing that hiatuses at the base of the OAE2 CIE in the central WIB sites account for the discrepancies (Eldrett et al., 2017; Li et al., 2017). With our new quantification of the hiatus at the base of the OAE2 CIE in the Portland Core and the addition of more continuous Os_i records in the Angus and SH#1 cores, it is possible to assess this hypothesis more critically. Additionally, a recent Os_i chemostratigraphy of the CTB succession in the Iona-1 Core (Sullivan et al., in press) provides another distinct profile to correlate and compare records from Utah and Colorado to Texas.

When the records from the central WIB and the Iona-1 cores are aligned and correlated using $\delta^{13}\text{C}$ and Os_i excursions, there is strong overlap between the floating eccentricity bandpass astronomical time scales of OAE2 (Fig. DR5). Bandpass filtering of the short eccentricity (E_{2-3}) spectral peak in both the central WIB (Meyers et al., 2001; Jones et al., 2019) and Texas (Eldrett et al., 2015) detect approximately six E_{2-3} cycles from the CIE base to the top of the CIE plateau (i.e., short definition ~ 600 kyr) and seven to eight E_{2-3} cycles from the CIE base to the return to stable $\delta^{13}\text{C}$ values (i.e. long definition) (Fig. 5). Most other sites with relatively conformable records of OAE2 globally preserve a similar number of cycles (see figure 9 of Charbonnier et al., 2018). However, discrepancies in timing of the CIE emerge when comparing the central WIB sites to the traced short obliquity cycle ($O1$: ~ 50 kyr) time scale for the Iona-1 Core preferred by Eldrett et al. (2015), which reports a longer duration for OAE2 (Fig. DR5). Thus, since eccentricity-based time scales correspond well among the sites, it is likely that the reported discrepancy between the Texas and central WIB durations for OAE2 primarily arises not from

hiatuses, but from the usage of the less common O1 cycle to tune the Iona-1 Core record. This finding suggests that, despite the increased amplitude of obliquity forcing during the CTB (Meyers et al., 2012a; Charbonnier et al., 2018), the O1 cycle is less reliable for astronomical tuning of mid-Cretaceous stratigraphic datasets given markedly lower power in the La2004 and La2010 solutions than other astronomical terms (Laskar et al., 2004; Laskar et al., 2011; Wu et al., 2013). The hypothesis that minor offsets in durations of OAE2 records in the Eagle Ford, Tibet, and the central WIB originate from cyclostratigraphic techniques, as opposed to hiatuses or significant differences in local stratigraphic preservation of the event, is consistent with the presented finding of a relatively short-lived hiatus at the base of the OAE2 CIE in the Portland Core and GSSP locality.

In addition, the Eagle Ford record from the Iona-1 Core preserves two $\sim +1\text{-}2\text{‰}$ $\delta^{13}\text{C}$ excursions underlying the main body of OAE2 (Fig. 5) labelled as pre-cursor isotope events (PCEs). These PCE do not appear in the Portland Core $\delta^{13}\text{C}$ record, a feature that has been attributed to hiatuses in the central WIB (Eldrett et al., 2015; 2017). However, the Os_i excursion of OAE2 occurs below the PCEs in the Iona-1 Core (Sullivan et al., in press). When compared to the Os_i records of the central WIB, this chemostratigraphic relationship indicates another possibility: that the PCEs in the Iona-1 Core correspond to the “A” $\delta^{13}\text{C}$ peak for OAE2 of Pratt (1985) in the central WIB. The position of biostratigraphic markers in the last occurrence (LO) datums of the foraminifera *Rotalipora cushmani* and nannofossil marker *Axopodorhabdus albianus*, as well as equivalent durations for OAE2 from eccentricity bandpasses, support this scenario (Fig. 5). The Iona-1 Core may preserve two $\delta^{13}\text{C}$ peaks within the “A” interval due to a more stratigraphically expanded record compared to the Portland Core and Pueblo GSSP. Nonetheless, additional high-resolution $\delta^{13}\text{C}$ chemostratigraphic studies of the onset of OAE2 in

the WIB, such as in the conformable Angus Core (Fig. 3), are needed to further test the hypothesis that the PCEs correlate to the “A” CIE peak.

Radioisotope Geochronology of the Cenomanian-Turonian Boundary

The five new $^{40}\text{Ar}/^{39}\text{Ar}$ ages (Fig. 7) for bentonites B, C, and D from Nipple Creek, UT, Lohali Point, Arizona, and Pueblo, Colorado all overlap with recent $^{40}\text{Ar}/^{39}\text{Ar}$ ages from the WIB (Meyers et al., 2012b; Jicha et al., 2016). The new $^{40}\text{Ar}/^{39}\text{Ar}$ age for Bentonite B at Nipple Creek (NC-B) is also equivalent within uncertainty to the youngest zircon U-Pb data of the bentonite (Barker et al., 2011; Meyers et al., 2012b), indicating that these two radioisotopic chronometers are synchronized. The new age of Bentonite D from Nipple Creek (NC-D) overlaps within total temporal uncertainty of the $^{40}\text{Ar}/^{39}\text{Ar}$ age of Meyers et al. (2012b), but does not overlap with the other new age for Bentonite D at Lohali Point, Arizona (90-O-34) (Table 2). Its mean $^{40}\text{Ar}/^{39}\text{Ar}$ age is 230 kyr younger than the mean age from Meyers et al. (2012b) and 357 kyr younger than the ash at Lohali Point (Fig. 7). Thus, the NC-D date represents an outlier and we exclude it from calculations of the age of the CTB.

When anchored to the short eccentricity traced floating astronomical time scale for the Portland Core (Meyers et al., 2001), the new $^{40}\text{Ar}/^{39}\text{Ar}$ dates for bentonites B (NC-B), C (NC-C, K-07-01C), and D (90-O-34-D) produce numerical age estimates for the Cenomanian-Turonian boundary (Table 2, Table DR1 in Data Repository). The 2σ uncertainties on individual CTB age estimates derive from the full radioisotopic, stage boundary placement (± 25 kyr), and astrochronologic (± 25 kyr) sources of uncertainty combined in quadrature (*sensu* Sageman et al., 2014b). The weighted mean age and 2σ uncertainty for the CTB from all four anchoring scenarios

for new dates is 94.05 ± 0.08 Ma. If we include all recent $^{40}\text{Ar}/^{39}\text{Ar}$ dates for these bentonites and U-Pb dates that do not exhibit evidence for inheritance (Barker et al., 2011; Meyers et al., 2012b; Eldrett et al., 2015; Jicha et al., 2016), the weighted mean CTB age is 93.95 ± 0.05 Ma. The CTB age estimate from the four new $^{40}\text{Ar}/^{39}\text{Ar}$ dates of this study is within uncertainty of recent radioisotopically calibrated ages reported for the boundary (Barker et al., 2011; Meyers et al., 2012b; Eldrett et al., 2015). However, the weighted mean age options proposed for the CTB from the new bentonite dates and from the compilation of new and recent dates (Fig. 7) are nominally older than the Meyers et al. (2012) age used for the CTB in the Geologic Time Scale (GTS) 2012 (Ogg and Hinnov, 2012) by 150 kyr and 50 kyr, respectively.

Although the new radioisotopically anchored and astronomically tuned age estimate for the CTB from southern Utah is consistent with existing geochronologic records, the onset age for OAE2 differs with the record from Texas. The U-Pb anchored astronomical time scale from the Iona-1 Core in the Eagle Ford of Texas places the age of the base of OAE2 ~ 300 kyr older (94.8 - 94.9 Ma) (Eldrett et al., 2015; Eldrett et al., 2017) than the records of the central WIB (94.55 ± 0.16 Ma) (this study) and the Yezo Group, Japan (Du Vivier et al., 2015b). Several studies spanning a wide range of ages demonstrate that the astronomical calibration of the FCs standard at 28.201 Ma (Kuiper et al., 2008) yields $^{40}\text{Ar}/^{39}\text{Ar}$ dates that are indistinguishable from, or slightly younger than, CA-ID-TIMS (chemical abrasion-isotope dilution thermal ionization mass spectrometry) U-Pb dates from zircons in the same, or correlative, rocks (e.g., Meyers et al., 2012b; Rivera et al., 2014; Sageman et al., 2014b; Singer et al., 2014; Andersen et al., 2017). This is true unless the U-Pb zircon dates show clear patterns of inheritance (e.g., Wotzlaw et al., 2013) as is the case for 8 of the 10 ash beds for which Eldrett et al. (2015) report U-Pb dates. It is thus unlikely that the disagreement between our new date for the onset of OAE2 from the central WIB and the U-Pb age

reported by Eldrett et al. (2015) in the Iona-1 Core reflect miscalibration of the $^{40}\text{Ar}/^{39}\text{Ar}$ chronometer. Rather, we suspect that pre-eruptive zircon crystallization or inheritance biases most of the U-Pb dates from the Eagle Ford to older ages, as several ash beds appear anomalously old and do not obey stratigraphic superposition (Eldrett et al., 2015). Meyers et al. (2012b) also previously noted inherited zircons based on U-Pb dating of several bentonites in the central WIB. Alternatively, this offset between the proposed initiation ages for OAE2 may result from the use of the O1 cycle for tuning the age-depth model in the Eagle Ford, as discussed above.

Eustatic Lowstand Preceding OAE2

Spatial variability in the development of hiatuses locally in the WIB underscores an undulating nature to bathymetry of the epeiric seaway, even within the same structural zones of the basin, such as the “axial basin.” Modern shallow marine foreland basins, such as the Persian Gulf Basin, exhibit analogous local variation in bathymetry linked to long-lived geologic structures (Kassler, 1973). Similarly, we posit that some deformation of the Rock Canyon Anticline could have occurred during the Cretaceous and contributed to local shoaling, exposing the bathymetric high to wave base mixing and winnowing during sea level lowstands.

The basal OAE2 hiatus at the GSSP locality and Portland Core occurs within the uppermost ammonite *Metoicoceras mosbyense* Biozone, and has previously been interpreted to represent a minor lowstand in the WIB (Sageman, 1985; Arthur and Sageman, 2005; Gale et al., 2008). Along the western margin of the basin in southern Utah, the shoreline progrades ~150 km east (“S1” genetic sequence in Fig. 2) and a regression incises ~10 m of strata below the OAE2 CIE at some sites (Uličný, 1999; Laurin et al., 2019). Therefore, the basal OAE2 hiatus at the Pueblo GSSP

locality and Portland Core may represent Late Cenomanian winnowing of a bathymetric high during a minor lowstand in the basin. Similarly, intervals of the middle Hartland Shale contain thin beds of winnowed skeletal limestones that correlate shoreward to a clastic wedge, suggesting another lowstand (Sageman, 1985, 1996). Bone beds, such as the one reported from the basal OAE2 hiatal surface at the Pueblo GSSP locality (Eicher and Diner, 1989), commonly correspond to transgressive surfaces in sequence stratigraphic models of epeiric seaways (Brett, 1995). Thus, the thin bone bed at the GSSP locality could instead represent a condensed bed that correlates to sediment starvation during the transgression overlying genetic sequence S1 of Utah (equivalent to Unit 6B of Uličný, 1999). Regardless of whether the hiatus corresponds directly to winnowing during relative sea level fall or condensation from the immediately subsequent transgression, the pre-OAE2 hiatus and shoreline trajectories in the WIB are reasonably interpretable as associated with a lowstand sequence boundary.

Moreover, a compilation of global relative sea level records, constrained by ammonite biostratigraphy and/or $\delta^{13}\text{C}$ chemostratigraphy, reveals coeval sequence boundaries and lowstands underlying OAE2 at many localities, including: the English Chalk (Gale et al., 1993), the Paris Basin (Robaszynski et al., 1998), Germany (Voigt et al., 2006; Richardt et al., 2013), Czech Republic (Uličný et al., 1997), Peru (Navarro-Ramirez et al., 2016), Mexico (Elrick et al., 2009), southern New Mexico (Mack et al., 2016), the northern Gulf of Mexico (Lowery et al., 2017), Jordan (Wendler et al., 2014), Lebanon (Grosheny et al., 2017), Israel (Buchbinder et al., 2000), Egypt (Nagm et al., 2014), and Morocco (Kuhnt et al., 2009). Consistency among these global Upper Cretaceous relative sea level records ties the hiatus in the uppermost Hartland Shale in the WIB to an apparent eustatic lowstand preceding the onset of OAE2, coeval with or just preceding a major pulse of LIP volcanism (Fig. 8). The link between LIP initiation and eustatic lowstand is

consistent with original hypotheses of volcano-tectono-eustatic feedbacks at the onset of OAE2, followed by eustatic transgression with expanded shelfal area and organic carbon deposition (Arthur et al., 1987). However, eccentricity pacing of relative sea level through the event along the western margin of the seaway indicates at least a partial background control from climatic processes as well (Jones et al., 2019; Laurin et al., 2019).

Refined Timing of LIP Volcanism and the OAE2 Carbon Cycle Perturbation

The apparently conformable Os_i chemostratigraphy from the Angus Core, with its high-resolution astronomical and radioisotopic time scale, provides a refined timeline of LIP volcanic activity in relation to the carbon cycle perturbation at the onset of OAE2 (Figs. 5, 8). Globally, all Os_i records of OAE2, including from the WIB, exhibit a geologically rapid increase in the flux of hydrothermal/volcanic osmium to the marine realm (Turgeon and Creaser, 2008; Du Vivier et al., 2014; Du Vivier et al., 2015b; Schröder-Adams et al., 2019; Sullivan et al., in press). In the case of the astronomically tuned record from the Angus Core, the precipitous unradiogenic Os_i excursion occurs abruptly in less than 20 kiloyears beginning 60 kiloyears before the CIE, with a subtle decrease in Os_i preceding the main Os_i excursion, 80-100 kiloyears before the CIE (Figs. 2, 5, 8). Assuming that a massive increase in the hydrothermal/mantle C flux coincided with this rapid hydrothermal Os pulse (e.g., Kuroda et al., 2007), carbon release to the ocean-atmosphere system on this time scale would have occurred rapidly enough to potentially alter marine carbonate chemistry (Du Vivier et al., 2015a) (Fig. 8).

The positive carbon isotope excursion marking the onset of OAE2 occurred only after a significant temporal lag following the abrupt onset of LIP volcanism, on the order of 10s of

kiloyears. This study quantifies that lag at 59 ± 10 kiloyears using the astronomical time scale for the Angus Core (see Results, Figs. 4-5, 8), a similar, though slightly longer duration than previous estimates (Turgeon and Creaser, 2008; Du Vivier et al., 2015a). Fundamentally, this lag represents the time between (1) the onset of massive submarine LIP volcanism, CO₂ degassing, and delivery of reduced metals to the marine realm; and (2) the carbon cycle perturbation of OAE2 recorded in $\delta^{13}\text{C}$ records, which ultimately reflects the spread in areal extent of anoxic and sulfidic marine bottom waters and burial/preservation of organic carbon (Scholle and Arthur, 1980; Owens et al., 2013).

The duration of the lag exceeds interpreted oceanic mixing time scales by an order of magnitude and, therefore, cannot solely represent the time needed to circulate water masses rich with biolimiting nutrients derived from submarine volcanic or continentally weathered sources, even in a sluggish mid-Cretaceous ocean (e.g., Turgeon and Creaser, 2008). It is possible that osmium cycle proxies (i.e., Os_i) are more sensitive to submarine LIP volcanism than carbon cycle proxies, and we have overestimated the pace of LIP CO₂ outgassing; tens of kiloyears could have been needed to accumulate CO₂ in the atmosphere. However, OAE2 preserves one of the longest-lived and most abruptly initiated unradiogenic Os_i excursions known from the Phanerozoic, suggesting a rapidly initiated and long-lived episode of prolific volcanism.

Alternatively, circulation of the marine dissolved oxygen reservoir typically provides a buffer against the prolonged expansion of anoxic bottom waters and organic carbon burial exhibited during OAEs. The inertia between volcanic CO₂ input and widespread anoxia/carbon burial likely represents the globally-averaged drawdown of this substantial marine oxygen reservoir during OAE2. Accordingly, the presented duration of the Os-C lag is equivalent to the duration of a gradual drawdown of redox sensitive trace metals and bottom water oxygen levels at

Demerara Rise (tropical Atlantic) which precedes OAE2 (Hetzl et al., 2009; Ostrander et al., 2017). The subsequent global-net enhanced burial and accumulation of organic carbon only drove the OAE2 CIE following this 10's of kyr deoxygenation process (Fig. 8). This implies that the preservation of organic carbon due to anoxic/euxinic bottom and pore waters, mediated by organic matter sulfurization (Raven et al., 2018), was a key paleoceanographic feedback that ultimately triggered the OAE2 CIE (Mort et al., 2007), perhaps more so than the initial increases in marine primary productivity.

Multiple Volcanic Pulses

In addition to a volcanic pulse preceding OAE2, ^{192}Os concentrations increase in the interval underlying Bentonite A, consistent with a second episode of submarine volcanism (Table 1; Figs. 3-4). In this interval within the upper half of the Os_i excursion in the WIB, already unradiogenic Os_i values at each site decrease further, subtly but consistently, and by more than analytical uncertainty. Values of Os_i decrease in the SH#1, Angus, and Portland cores respectively by 0.066, 0.026, and 0.053 below Bentonite A (Table 1; Figs. 3-5). Thus, the WIB osmium chemostratigraphy indicates that the LIP emanated at least two pulses of volcanic activity that punctuated an elevated background rate of volcanism spanning the onset and the early interval of OAE2 (Fig. 8). Similar scenarios of multiple pulses of volcanism (Sullivan et al., in press) and anoxia (Jenkyns et al., 2017; Clarkson et al., 2018) during the event have been reported, hinting at links between the intensity of volcanism and marine deoxygenation, although correlations appear to exhibit offsets in the precise timing of these processes.

Re-Os Geochemical Dynamics in an Epeiric Seaway

The proximal-distal transect of the mid-latitudes of the WIB constrains spatial variability of Os_i chemostratigraphic records in a shallow continental seaway through a period of massive volcanism and eustatic transgression. Osmium chemostratigraphy of both Quaternary and Cenomanian-Turonian records exhibit a degree of spatial variability in Os_i composition among oceanic basins, highlighting the sensitivity of a given locality's record to water mass heterogeneity and the proximity of weathered sources of osmium (Du Vivier et al., 2014; Du Vivier et al., 2015b; Rooney et al., 2016). Despite fluctuating sea level in the WIS and likely some degree of basin restriction, the unradiogenic Os_i excursion and enrichment in ^{192}Os at the onset of OAE2 is robustly preserved in each of the three sites transecting the depositional settings in the basin, heralding a pulse of LIP volcanism (Fig. 5).

Values of Os_i are equivalent across the basin during the syn- and post-OAE2 intervals, including at the most proximal locality - SH#1 (Fig. 6). However, Os_i values in the SH#1 Core are highly radiogenic prior to OAE2 compared to sites in the axial basin, at a time when the shoreline of the western margin of the seaway was closer to the site (~35 km, cf. Laurin and Sageman, 2007). The radiogenic values in this interval reflect the proximity of continentally weathered Os sources in the Sevier Belt. It appears that when the shoreline was within 10's of kilometers of the site, the Os_i proxy was sensitive to runoff from the Sevier Belt, whereas when the shoreline was more than ~100 km away, the proxy tracked values of Os_i that characterize the broader seaway and pelagic marine records. Nonetheless, the pre-OAE2 interval at SH#1 exhibits a shift to unradiogenic values below the major Os_i excursion (Fig. 3), similar to records globally (Du Vivier et al., 2014; Du Vivier et al., 2015b). These findings indicate that the proxy remains sensitive to major changes in the global fluxes of the marine Os cycle in proximal marine settings during LIP episodes, despite offsets in the absolute values of Os_i trends.

551

552 **CONCLUSION**

553 Our new chemostratigraphic compilation from the Angus and SH#1 cores spans the onset
 554 of OAE2 in the WIB. The proximal-distal transect defines spatial variability and local controls on
 555 the Re-Os proxy for volcanism in a semi-restricted epeiric seaway. Observations support prolific
 556 LIP volcanic activity in the Late Cenomanian, most likely in the Caribbean and Arctic regions.
 557 Notably, the characteristic unradiogenic Os_i chemostratigraphic marker of volcanism preceding
 558 OAE2 extends to SH#1, the most proximal setting studied in the WIB.

559 New $^{40}\text{Ar}/^{39}\text{Ar}$ dates for traceable bentonites in the WIB, combined with recently published
 560 radioisotopic analyses, yield an astronomically calibrated age for the Cenomanian-Turonian stage
 561 boundary of 93.95 ± 0.05 (2σ) Ma, which is consistent with other recent age estimates but slightly
 562 older than the GTS 2012 age. The integrated radioisotope geochronology, astrochronology,
 563 chemostratigraphy, and biostratigraphy from the WIB provide a high-resolution age model
 564 refining the chronology of triggers and paleoenvironmental feedbacks for OAE2. Most notably, a
 565 59 ± 10 kyr lag between intensification of LIP volcanism and widespread, globally-averaged
 566 organic carbon burial is quantified at the onset of OAE2. This lag during the initial phase of
 567 volcanism suggests net-deoxygenation of the global ocean over tens of kiloyears, past a threshold
 568 for widespread organic C preservation, was a critical process in the ultimate initiation of OAE2.
 569 Further, the rapid onset of LIP volcanism preceding OAE2 is consistent with a scenario of
 570 increased $p\text{CO}_2$, altered marine carbonate chemistry, and decreased aragonite/calcite saturation
 571 levels in the global ocean (Du Vivier et al., 2015a). Additionally, a second pulse of LIP volcanism
 572 ~ 100 kyr after the onset of the CIE is consistent with earlier investigations.

The refined chronostratigraphic framework is also used to assess stratigraphic conformability and correlation of reference sites for the CTB in the WIB. The duration of a hiatus in the crucial onset interval of OAE2 at Pueblo, CO (Base Turonian GSSP) and the Portland Core is equivalent to the geologically brief temporal lag between volcanism and carbon cycle perturbation. This hiatus is associated with a minor eustatic lowstand and subsequent transgression preceding OAE2, recorded in many shallow marine settings globally, which is potentially linked to tectonic or climatic feedbacks from the coeval initiation of LIP volcanism. Based on Os_i chemostratigraphic correlation, minor $\delta^{13}\text{C}$ excursions underlying the main OAE2 CIE in the Eagle Ford of Texas appear to correspond to the “A” segment of the $\delta^{13}\text{C}$ record in the central WIB. Additionally, residual offsets in recent time scales for OAE2 may originate in part from biases in radioisotope geochronology, such as zircon inheritance, and/or differences in astrochronologic tuning methodologies and chemostratigraphic definitions of the event.

ACKNOWLEDGEMENTS

We thank: Antonia Hofmann, Geoff Nowell, and Chris Ottley for assistance with Re-Os geochemical analyses; Steve Meyers for providing the ATS for the Portland Core; Bryan Wathen for mineral separation; Rosie Oakes, R. Mark Leckie, Julio Sepulveda, Tim Bralower, Scott Karduck, and Amanda Parker for assistance logging and sampling the SH#1 Core; R. Mark Leckie, Jiří Laurin, and David Uličný for insightful discussions on the stratigraphy of the Kaiparowits Plateau; Brad Cramer and an anonymous referee for constructive reviews improving the quality of the manuscript; the USGS for drilling the SH#1 Core; and Encana for donating the Angus Core to Northwestern University. This article represents a portion of the doctoral research of MMJ at Northwestern University. BBS acknowledges funding from NSF Earth-Life Transitions grant

596 #1338312 and thanks the U.S. BLM for sample collection permit 9560 (UT-030). DS
597 acknowledges funding from the TOTAL Endowment Fund and the Dida Scholarship.

Figure Captions

Figure 1. Early Turonian map of North American Western Interior Basin marking primary localities of cores investigated or discussed in this study (adapted from Roberts and Kirschbaum, 1995; Ma et al., 2014). AZ-Arizona, USA; CO-Colorado, USA; GSSP-global boundary stratotype section and point; NC-Nipple Creek outcrop; SH#1 – Smoky Hollow #1 Core.

Figure 2. Lithostratigraphy and ammonite biostratigraphy of the Cenomanian-Turonian boundary interval in the Western Interior Basin from central Colorado to southern Utah (modified from Tibert et al., 2003). Regional bentonites of Elder (1988) and Leithold (1994). Shoreline trajectory of genetic sequences scaled versus age (modified from Laurin et al., 2019). Ls.-limestone; OAE2-Oceanic Anoxic Event 2; Ss-sandstone; GSSP-global boundary stratotype section and point; SH#1 – Smoky Hollow #1 Core.

Figure 3. Chemostratigraphy of the Angus Core. From left to right: wt.% carbonate content and wt.% total organic carbon (TOC) (open circles = new data in Data Repository, black/blue circles from Joo and Sageman, 2014), bulk organic carbon isotopic ratios $\delta^{13}\text{C}_{\text{org}}$ (Joo and Sageman, 2014), initial osmium isotope ratios Os_i , rhenium concentrations (green circles), 192-osmium concentrations (orange squares) (Table 1). Mbr.-member; OAE2-Oceanic Anoxic Event 2.

Figure 4. Chemostratigraphy of the Smoky Hollow (SH#1) Core in southern Utah. From left to right: wt.% carbonate content, wt.% total organic carbon (TOC), and bulk organic carbon isotope ratios ($\delta^{13}\text{C}_{\text{org}}$) from Jones et al. (2019); $^{40}\text{Ar}/^{39}\text{Ar}$ bentonite ages, initial osmium isotope ratios (Os_i), rhenium concentrations (green circles), and 192-osmium concentrations (orange squares) from this study. $^{40}\text{Ar}/^{39}\text{Ar}$ bentonite dates correlated from the nearby Nipple Creek outcrop section. Stratigraphic column, correlated ammonite biostratigraphy, bentonite stratigraphy, and

1075 Cenomanian-Turonian boundary placement updated (see Fig. DR3 in Data Repository) from Jones
 1076 et al. (2019). See text for discussion. Lithology legend in Fig. 5. Fm.-formation; fs-flooding
 1077 surface; OAE2-Oceanic Anoxic Event 2; VPDB-Vienna Pee Dee belemnite; P.f.-
 1078 *Pseudaspidoceras flexuosum*.

1079 **Figure 5.** Initial osmium isotope records of the Western Interior Basin. Stratigraphic columns for
 1080 the SH#1 Core (updated from Jones et al., 2019), Angus Core (this study), Portland Core near
 1081 GSSP (Meyers et al., 2012b), and Iona-1 Core from the Maverick Basin, Texas (redrafted from
 1082 Eldrett et al., 2015) (L-R). Bentonite labels A-D in red for central WIB sites; these bentonites may
 1083 be present in the Iona-1 Core of Texas, however, they were originally reported to pinch out in New
 1084 Mexico before reaching Texas (Elder, 1988), complicating exact bentonite correlations to the Iona-
 1085 1 Core. Bandpass filters for the SH#1 (Jones et al., 2019), Angus (Ma et al., 2014), Portland
 1086 (Meyers et al., 2012b), and Iona-1 cores (Eldrett et al., 2015). Quantified durations of Portland
 1087 Core/GSSP hiatuses from Meyers and Sageman (2004) and this study (see Results). Carbon
 1088 isotope ($\delta^{13}\text{C}_{\text{org}}$) chemostratigraphy in black for the SH#1 (Jones et al., 2019), Angus (Joo and
 1089 Sageman, 2014), Portland (Sageman et al., 2006; Du Vivier et al., 2014), and Iona-1 cores (Eldrett
 1090 et al., 2015) define the OAE2 excursion (dark grey shading=short, end of plateau definition; light
 1091 grey and dark grey shading=long definition). Initial osmium isotope ratios (Os_i) (open circles/red
 1092 line) preserve unradiogenic (hydrothermal/LIP) excursion underlying OAE2 for SH#1 and Angus
 1093 cores (this study), Portland Core (Du Vivier et al., 2014), and Iona-1 Core (Sullivan et al., in press).
 1094 Fm.-formation; OAE2-Oceanic Anoxic Event 2.

1095 **Figure 6.** Timeseries of $\delta^{13}\text{C}_{\text{org}}$ and Re-Os geochemical records from the SH#1 (light red), Angus
 1096 (blue), and Portland (black) cores through OAE2. Break in Portland Core timeseries during lag
 1097 (grey) signifies hiatus. From left to right, figure plots bulk carbon isotope ratios ($\delta^{13}\text{C}_{\text{org}}$), initial

osmium isotope composition (O_{Si}), osmium-192 concentration, and rhenium concentration. Timeseries for Angus Core from astrochronology (Ma et al., 2014), Portland Core from astrochronology (Meyers et al., 2001) and linear interpolation of ammonite biozones below hiatus (this study), and SH#1 Core from astrochronology (Jones et al., 2019) and linear interpolation of sedimentation rates below OAE2 CIE. See text for methods and discussion. OAE2-Oceanic Anoxic Event 2.

Figure 7. Left - Plot of all recent $^{40}\text{Ar}/^{39}\text{Ar}$ (circles) and CA-ID-TIMS U-Pb (squares) ages for the B, C, and D bentonites in the Western Interior Basin. Right - recent age estimates for the Cenomanian-Turonian boundary (CTB), including the GTS2012 age from Meyers et al. (2012b). Filled circles represent data from this study. All data are shown with 2σ full external uncertainties. Note that U-Pb dates of Meyers et al. (2012b) from Lohali Point, Arizona for bentonites C and D are not plotted due to the presence of inherited zircons, similar to trends exhibited in several plotted U-Pb ages for Bentonite B. The Eldrett et al. (2015) youngest zircon date for bentonite “B4” is from a horizon that is 0.5-1.0 short eccentricity cycle below where they place Bentonite B and thus is not considered further when discussing age calculations (see Eldrett et al., 2015 supplement for details). The age from “Bighorn River (n=6)” corresponds to the age derived from all six zircons analyzed from the bentonite sample, whereas “Bighorn River (n=3)” corresponds to the youngest three zircon ages from the horizon (Barker et al., 2011). Several samples possessing inherited zircons or considered outliers (diamonds) are not included in the calculation of the weighted mean age of the Cenomanian-Turonian boundary for this study (grey shading and dashed line). See text, Table 2, and Table DR1 in Data Repository for determination of the CTB age.

Figure 8. Refined conceptual timeline of OAE2. From left to right – sea level history during OAE2 (Jones et al., 2019) and isotopic records of osmium (this study), calcium (Du Vivier et al., 2015a), thallium (Ostrander et al., 2017), and carbon (Joo and Sageman, 2014) as proxies for LIP volcanic activity, carbonate chemistry, marine deoxygenation, and carbon cycle response of organic carbon burial, respectively. Dashed line in $\delta^{44}\text{Ca}$ profile reflects missing time in Portland Core. Data from other sites and within and outside WIB confirm coincident timing of $\delta^{44}\text{Ca}$ and Os_i excursions. See text for discussion.

Notes:

Ages calculated relative to 28.201 Ma Fish Canyon sanidine (Kuiper et al. 2008) using decay constants of Min et al. (2000)

^a Age uncertainty includes analytical uncertainty + J uncertainty.

^b Total age uncertainty includes decay constraint, standard age, J, and analytical uncertainties.

^c CTB age calculated by anchoring Portland Core astronomical timescale to ash date

^d CTB age uncertainty includes radioisotopic, stage boundary placement, and astrochronological time scale uncertainties combined in quadrature.

For single crystal incremental heating experiments, N = number of plateau ages/number of experiments

For single crystal fusion data, N = number of dates included in weighted mean/number of fusions

Ages for the Cenomanian-Turonian Boundary are calculated by anchoring the floating astronomical time scale of the SH#1 Core to the new $^{40}\text{Ar}/^{39}\text{Ar}$ ages (see text for discussion).

CTB age (Ma)^c ±2σ^d

n/a	n/a
94.129	± 0.156
93.914	± 0.156

94.140	± 0.207
94.065	± 0.158
